Abstract

The purpose of the present study was to evaluate the prevalence of teeth malposition (rotated) in Brazilian patients with oral clefts and to contribute to the definition of subphenotypes. This study included 317 patients with nonsyndromic cleft lip with or without cleft palate. Tooth malposition was assessed clinically, through radiographs, and medical history records for each individual. Only teeth malpositions outside the area of the clefts were included. Comparisons were assessed by cross-tabulation and standard chi-square test, and statistical significance was set at ps0.05. Cleft lip and palate was more prevalent in males, while cleft palate was more common in females. Regarding the presence of tooth malposition, of the 317 patients, 92 (29.02%) had at least one tooth with the dental anomaly. Tooth malposition was more common in patients with cleft lip and palate (16.1%), followed by, respectively, cleft palate (6.9%) and cleft lip (6%) (p=0.112). The highest occurrence of tooth malposition was in the mandible and involved the canines (p<0.01). Few studies have investigated the prevalence of tooth malposition in individuals with nonsyndromic cleft lip with or without cleft palate. Our results confirmed the highest occurrence of dental anomalies, particularly tooth malposition, in patients with oral clefts. Our findings also highlight that there was a higher occurrence of this condition in the mandible and not the maxilla.

Introduction

The embryological development of the face relies on the interplay of a vast range of factors encompassing cell differentiation, growth, apoptosis, cell to cell adhesion, and inter and intracellular signaling. The disruption of a gene that controls one or more of these factors, inhibition of cell function by environmental teratogens or a combination of the two is likely to be the etiological cause of craniofacial malformations such as nonsyndromic cleft lip with or without cleft palate (NSCL/P) [1].

NSCL/P affects approximately 1/700 live births, with wide variability across geographic origin, racial and ethnic groups, as well as environmental exposures and socioeconomic status. In general, Asian and Amerindian populations have the highest reported birth prevalence rates, often as high as 1/500, European-derived populations have intermediate prevalence rates at about 1/1,000, and African-derived populations have the lowest prevalence rates at about 1/2,500 [2]. In Brazil, the prevalence is between 0.36 and 1.54 per 1,000 live births. Cleft lip and palate (CLP) is most frequent in males and isolated cleft palate (CP) is most typical in females [3]. Individuals with CLP may experience problems with feeding, speaking, hearing and social integration that can be corrected to varying degrees by surgery, dental treatment, speech therapy and psychosocial intervention [2]. It has been proposed that clefting is part of a complex malformation associated with other dental anomalies resulting from a disturbed dentition development [4]. Recent studies proposed that dental anomalies outside of the cleft area could serve as clinical markers for the definition of cleft subphenotypes, suggesting a common genetic background between such conditions [5–9]. In favor of this hypothesis is the fact that tooth, lip, and palate development occur almost concomitantly and are related anatomically [10–12]. When compared with the general population, dental anomalies, such
as tooth agenesis, supernumerary teeth, microdontia, fused teeth, ectopic eruption, tooth malposition (rotation), taurodontism and enamel hypoplasia, are considerably more prevalent in individuals with NSCL/P [5-8,13-15]. In addition, few studies have investigated the dental anomalies associated with subphenotypes of oral clefts, justifying the importance of this study.

Tooth malposition (rotation or inclination), was considered subjectively as any evident (at least 20°) mesiolingual or distolingual intra-alveolar displacement of a tooth around its longitudinal axis [16]. The purpose of the present study was to evaluate the prevalence of tooth malposition in patients with oral clefts and to contribute to the definition of NSCL/P subphenotypes.

Material and Methods

This study included 317 patients with repaired NSCL/P. All participants were recruited from the same institution (Centre for Rehabilitation of Craniofacial Anomalies, Minas Gerais State, Brazil). All subjects were from Minas Gerais, Brazil, where there is an admixed population of Europeans (mostly from Portugal and Italy) and Africans, with a small percentage of native Brazilian Indians. All patients presented similar ethnicities and social culture.

Teeth were assessed clinically, through panoramic radiographs, and medical history records for each individual. The radiographs were examined with magnifying glass in a dark room over a light box that had a frame to avoid light passing on the sides of the radiograph. Eruption of any tooth in an abnormal position was the criteria considered to represent malposition. Patients with a history of dental extraction, previous orthodontic treatment, or who were younger than 12 years old were excluded due to the inability to accurately identify all anomalies. In order to eliminate inter-examiner differences, dental anomalies were classified by a single calibrated examiner (intra-examiner Kappa value = 0.93). We did not include primary dentition nor third molars. Only teeth malposition outside the area of the clefts were included in this study.

The clefts were categorized into three groups with the incisive foramen as a reference: (1) Cleft Lip (CL): includes complete or incomplete pre-foramen clefts, either unilateral or bilateral; (2) Cleft Lip and Palate (CLP): includes unilateral or bilateral transforamen clefts and pre- or post-foramen clefts; (3) Cleft Palate (CP): includes all post-foramen clefts, complete or incomplete [17]. Median or rare clefts were not included in our analysis.

The information collected was stored in a database and analyzed using the statistical program SPSS® version 19.0 (Statistical Package for Social Sciences for Windows, Inc., USA). Comparisons were assessed by cross-tabulation and standard chi-square test, and statistical significance was set to p≤0.05. This study was approved by the University’s Ethics Committee in Research.

All patients were informed about the study’s purpose before they provided written consent to participate.

Results

Of the 317 subjects included in this study, 172 were male and 145 were female. The average age was 17.48 years old. Table 1 shows the distribution of the types of oral clefts according to extension and gender. Of the 317 patients with clefts, 189 had CLP, 74 had CL, and 54 had isolated CP. CLP was more prevalent in males, while CP was more common in females. CL had a similar distribution between the genders. With regard to skin color, most of the patients were non-Caucasian (209, 65.93%; 108 or 34.06% were Caucasian).

Regarding the presence of tooth malposition, of the 317 patients, 92 (29.02%) had at least one tooth with the dental anomaly. Of these 92 patients with tooth malposition, 144 teeth presented the anomaly. This means that 40 patients had more than one tooth with malposition. Table 2 shows the frequency of patients with tooth malposition according to the types of oral clefts. It turns out that tooth malposition was more common in patients with CLP (16.1%), followed...

by CP (6.9%) and CL (6%) (p=0.112).

In Table 3, it is possible to assess the distribution of tooth malposition according to their anatomical location (maxilla or mandible). When evaluating the 144 teeth malposition, it can be observed that most (69.48%) are located in the mandible. Most mandibular malposition was in the canines (53.47%), followed by the second premolars (6.25%). In the maxilla (30.54%), the highest occurrence of malposition was seen in lateral incisors (9.72%), followed by the central incisor (9.03%).

Discussion

Certain evidence suggests that the phenotype of NSCL/P is much more complex than commonly believed. For that reason, thorough knowledge of its various possible combinations, especially concerning the cleft extension and presence of dental anomalies in areas outside of the cleft, is important. Out of 317 patients evaluated in the present study, 92 (29%) presented tooth malposition. This result confirms that dental anomalies in NSCL/P patients are more frequent than in healthy Brazilian individuals [7,18]. Recently, we found 39.9% of Brazilian patients with NSCL/P present dental anomalies. Tooth agenesis (47.5%), impacted tooth (13.1%), and microdontia (12.7%) were the most common anomalies [8].

In the present study, there was a higher prevalence of tooth malposition in the mandible compared to the maxilla (p<0.01). Similar to the study mentioned above [5], the mandibular canines were the most affected teeth (53.47%). The observation of malposition, with mandibular canines being the most affected teeth and often associated with CLP, is noteworthy and has not yet been described [5]. Our results agree with these findings. Although the occurrence of tooth malposition could be explained as a consequence of plastic surgery for repair of the oral clefts, which can affect the development of maxillary bone resulting in less space in the upper arch for normal eruption of teeth [23], it is interesting to mention that the higher incidence of this dental anomaly occurred in the mandible and not the maxilla.

Tooth malposition in patients with cleft lip and/or palate in a Brazilian population

When analyzing the cleft type distribution by gender, we found a higher prevalence in males, mainly in CLP, and a higher prevalence of isolated CP in females. These results are concordant with previous studies [6,23-25]. Previous reports have established that oral clefts present a sexual dimorphism: CLP is more common in males and CP is prevalent in females [3,7,25]. Here our results are similar to those found in the literature, but the occurrence of CL isolated was equal in both genders.

As the Brazilian population is result of the genetic admixture of three main ancestral populations (Europeans, Africans, and Amerindians) and displays very high levels of genomic diversity [26], we have previously demonstrated that the use of ancestry markers in association studies of ethnically mixed populations (structuration of the samples) is important to avoid interpretation bias [27,28]. In this study, the characteristics of the ancestry of the studied population (Minas Gerais State, Brazil) were previously evaluated [29].

Few studies have investigated the prevalence of tooth malposition in individuals with NSCL/P. Our results confirmed the highest occurrence of dental anomalies, particularly tooth malposition, in patients with oral clefts. Our study also highlights that there was a higher occurrence of this condition in the mandible and not maxilla. However, future studies are necessary to determine the exact mechanisms responsible for the occurrence of tooth malposition.
