Abstract

Background. Polymer bur is a new technology that proposes to conserve the dentin that is capable of remineralization. Aim: To conduct a quantitative systematic review to evaluate the effect of polymer burs on the reduction of Streptococcus mutans and Lactobacillus after dentin carious excavation in deciduous teeth. Methods and Material: Two reviewers performed the database to identify the relevant clinical papers. Only papers in English that performed similar polymer bur techniques were included. Results: The search resulted in 12 non-duplicated papers. The revision, only 2 were selected. The quantitative evaluation showed polymer bur reduces microorganism levels in carious dentin. Conclusion: Polymer burs promote a significant reduction of microorganism levels, mainly Streptococcus mutans in carious dentin.

Introduction

Dentinal caries is structurally divided into infected and affected dentin. The superficial layer is the infected dentin. It is irreversible denatured and extensively demineralized. The deeper layer is the affected dentin and is bacteria-free. It is potentially and physiologically remineralizable, with odontoblastic process, sound collagen fibers and apatite crystal bound to the fibers [1-6]. The minimally invasive dentistry concept implies that the infected and irreversibly denatured dentin should be removed selectively to preserve as much as possible or potentially remineralizable dentin [3,7]. However, a balance between tissue preservation and infected dentin removal should be achieved in order to prevent caries progression [4,8-9].

Conventional methods for carious dentin removal include manual excavation with hand excavators and burs associated with low or high-speed handpieces [10]. Both are dependent of the operator’s optical and tactile sensitivity and may lead to an unnecessary removal of dental tissues [5,8-12]. Moreover, infected and affected dentin have some differences such as in the hardness, toughness and resilience, which determine the relative efficiency of caries excavation techniques [2].

New techniques have been proposed to conserve dental tissue that is able to remineralize [2-3,6,10-11]. Polymer burs were developed (Smartbur-SS White Company - Lakewood, NJ, USA) to be used with conventional low-speed handpieces that propose a self-limiting technology, to provide selective caries removal. These burs are single-use instruments, made with a polymer that presents value of hardness Knoop (KHN) equal to 50. This hardness value is lower than healthy dentin (70-90), but
The effect of polymer burs on microbiological reduction of carious dentin in deciduous teeth: a systematic review

To conduct this review, the PRISMA STATEMENT checklist was used [14]. The study was registered in the international prospective register of systematic reviews “PROSPERO” (www.crd.york.ac.uk/PROSPERO) (registration number CRD42015016678).

**Search Strategy**

Using the following databases, the search of the literature was performed: MEDLINE (1966–February 2016), Web of Science (1900–February 2016), Scopus (1960–February 2016) and The Cochrane Library (1993–February 2016).

Attempts to obtain missing information, additional manual search were performed to find further papers that were not in the electronic databases. Reference lists from identified papers were scanned to identify other potentially relevant papers.

**Inclusion and Exclusion Criteria**

The inclusion criteria were as follows:

1. Papers in English.
2. Clinical papers.
3. Papers that evaluate the effect of the polymer burs on the reduction of microorganisms.
4. The outcome was to evaluate microbiological aspects.

**Materials and methods**

**Protocol and registration**

The exclusion criteria included the following:

1. Papers in vitro, ex-vivo, case reports, case series, studies with animal models and reviews.
2. Papers without comparison of the polymer bur with other technique.
3. Papers that evaluated only permanent teeth.

Unpublished results, thesis, book chapters, abstracts and reviews were not included.

Selection Criteria

All potentially relevant papers were identified by the title and the abstract. After that, the full text analyses were performed to include the paper in the systematic review.

Two examiners (DSBO and DB) evaluated titles, abstracts and full text. If there was a diverging opinion, disagreement among examiners was reexamined in consensus meetings.

Data extraction

One author (DSBO) extracted the relevant data from the included papers. From each included study, the description of the sample, the study design, microbiological evaluation and results were summarized in the table 1. Other author (ECK) checked the extracted data. Disagreements between the two researchers were resolved by discussion and consensus.

Assessment of risk of bias

The quality assessment of the remaining papers was performed to evaluate methodological aspects related to influence bias, to gain insight into the results of the techniques comparisons and to guide the interpretation of qualitative and quantitative findings.

Five criteria were used to analyze all included papers: 1) sample size calculation; 2) random allocation of the participants; 3) participants’ eligibility, 4) inclusion and exclusion criteria; 5) standardization of the investigator. Two of the reviewers (PNF and ECK) assessed the included papers for risk of bias and were blinded to each other's assessments. Disagreements were resolved through discussions with a third reviewer (RABS). Domains from the Cochrane Collaboration risk of bias tool were assessed for each study. Data were entered into Review Manager 5.3 (RevMan 5.3) for the graphical representation.

Calculation of the effect size

Comparisons of microorganism reduction before and after dentin carious excavation were performed for each study and each comparison group. In order to pool data, means and standard deviations were converted into

effect size. When the results were presented as median, the mean value and the standard was calculated using the formula proposed by Hozo et al. [15]. Individual study effect sizes for the 2 included papers, that presented the data as a continuous variable, were calculated using Cohen’s d formula [16]. Positive values represented a reduction of microorganism level. The effect-size was classified as suggested by Cohen [16], in low effect (d≤0.2), medium effect (0.21≤d≤0.79) and high effect (d≥0.8).

Results

A total of 132 titles and abstracts were screened from the selected databases. There were 110 in PubMed, 10 in Web of Science, 8 in Scopus and 4 in Cochrane. The duplicates were considered only once, totaling 132 papers.

Initially, the titles and abstracts not connected with the topic were excluded (116 papers). Afterwards, the papers were selected according to the inclusion and exclusion criteria, totaling 4 papers selected for full text analysis. After reading, 2 papers were excluded because they were in vitro papers. Thus, 2 full texts were included and analyzed according to the selection criteria (figure 1).

The summary of the characteristics of the two included papers is described in the table 1. The papers were also carefully read and ranked based on the risk of bias as shown in figure 2.

The quantitative analysis, that shows the effect size of microorganisms reduction, are presented in the table 2. All techniques demonstrated a moderate and large reduction of Streptococcus mutans and Lactobacillus levels. The larger effect size observed was for Streptococcus mutans in the polymer bur technique (r=0.84; d=3.12), followed by Lactobacillus in the carbide bur technique (r=0.83; d=3.03).

Discussion

The removal of infected carious dentin and the careful maintenance of the dentin that is capable of remineralization has been a focus of the conservative dentistry approaches [3]. The actual criteria for caries removal arise from the concept that
“sound” tissue or potentially remineralizable tissue should not be unnecessarily removed [5,17]. Nevertheless, the exact endpoint of caries removal cannot be easily clinically defined. This may be explained by the fact that dentists have been trained in relying on the hardness of dentine as felt with a dental probe. Other more subjective characteristics, such as the dentin color and moisture are often neglected [17]. Our quantitative systematic review aimed to evaluate a new technique that proposes to preserve the potentially remineralizable tissue without the dentist’s attention to the subjective characteristics.

An important criteria to differentiate infected dentin of affected dentin is the number of viable microorganisms existent in the remaining dentin [2-4,6]. Therefore we chose this parameter as an outcome to evaluate the effectiveness of the polymer burs to reduce cariogenic microorganisms. In the present study, the effect size calculation demonstrated that burs, polymer burs and spoon excavator were able to promote a moderate and a large microbiological reduction.

Mutans streptococci are the main etiologic agent of dental caries in humans [18-19], which explains the importance of its reduction after procedures of minimal invasive excavation. Indeed, we observed that polymer bur promoted the largest reduction in Streptococcus mutans levels.

Minimal-invasive dental preparation, such as polymer burs, simplifies and standardizes caries-removal procedures [17]. In fact, our results demonstrated that polymer burs may offer a viable and efficient means to achieve minimal-invasive dental preparation. Maintain the healthy dental structures as previously described [3-5].

Our results showed that the polymer burs were more effective in Streptococcus mutans removal, while conventional burs provided a further reduction of Lactobacillus. As conventional burs are more invasive than polymer burs and usually extends into the affected dentine [3,5,13], this might lead to a larger reduction of Lactobacilli which are strictly anaerobic, highly sensitive to pH raising and located in the deeper portions of the carious dentin [20-22].

The included papers have some limitations that directly reflect our review results. None of them attempted to perform a sample size calculation, and only one paper performed a random allocation of used teeth and the standardization of the investigator for the polymer burs use. In addition, it is important to emphasize that a long-term follow up should be perform in order to evaluate a real clinical efficiency regarding the caries lesion recurrence.

Although in all techniques evaluated in the included papers, there was reminiscent number of viable microorganisms in the deeper layers of dentin, we can assume that the subsequent sealing performed by the restoration could solve this issue, as previously demonstrated [23]. Therefore, the maintenance of the cavity sealing through a dentinoenamel junction free from caries and adhesive restorations would interrupt the communication of bacteria present in dentin with the surface biofilm, with a consequent reduction in nutrients and bacterial viability [24].
How does a polymer bur actually provide clinical benefits?

Although this study aimed to answer the question about the efficacy of the polymer burs for microorganism’s reduction during carious removal, it raises questions that should be considered by clinical researchers. Microorganisms reduction comparison does not necessarily allow the researchers and clinicians to infer which is the most effective method for minimal invasive approach. Furthermore, the use of polymer burs does not eliminate the need of conventional burs, which may be necessary for the enamel removal to access the carious dentin.

The polymer burs propose for the clinicians a less invasive option for deep decay removal, while leaving healthy dentin intact (Smartbur-SS White Company- Lakewood, NJ, USA). This study demonstrated that conventional methods and the polymer burs reduce levels of Streptococcus mutans and Lactobacillus. However, since the polymer burs are selective for carious dentin remove, it should be an option for clinicians to preserve sound dentin. In addition, it has been proposed that this technique may eliminate the use of local anesthesia. However, the researchers should largely investigate the clinical benefit of this new instrument.

Suggestion for Future Papers

Based on this systematic review, some questions should be answered in future papers. First, although it is accepted that the dental restoration is effective to deal with the microorganisms left in the remaining dentin, a long term follow up should be performed. Also, since there were no remarkable differences in microorganisms reduction among the minimal invasive techniques, future clinical papers should attempt to evaluate the effectiveness of the polymer bur in a multilevel design study, in which preparation time, peculiarities of this new technique, operator training, assessment of important clinical criteria such as pain, sensitivity to pressure, vibration and temperature changes and cost (single use instrument) of the polymer bur should be included.

Finally, definitive clinical conclusions about the effectiveness of polymer burs were not described in this paper as only one outcome, the microbiological, was evaluated. Other important parameters such as evaluation of hardness, color and humidity are important in assessing the carious dentin removal. Furthermore, papers evaluating the long-term remaining dentin are important to determine if the number of bacteria remaining after carious dentin removal with polymer burs will not be viable for the recurrence of caries. In conclusion, polymer burs promote the reduction of microorganism levels, mainly Streptococcus mutans.
